HERQ-9 Is a New Multiplex PCR for Differentiation and Quantification of All Nine Human Herpesviruses

Pyöriä, Lari ; Jokinen, Maija ; Toppinen, Mari ; Salminen, Henri ; Vuorinen, Tytti ; Hukkanen, Veijo ; Schmotz, Constanze ; Elbasani, Endrit ; Ojala, Päivi M ; Hedman, Klaus ; Välimaa, Hannamari ; Perdomo, Maria F

Abstract: Infections with the nine human herpesviruses (HHVs) are globally prevalent and characterized by lifelong persistence. Reactivations can potentially manifest as life-threatening conditions for which the demonstration of viral DNA is essential. In the present study, we developed HERQ-9, a pan-HHV quantitative PCR designed in triplex reactions to differentiate and quantify each of the HHV-DNAs: (i) herpes simplex viruses 1 and 2 and varicella-zoster virus; (ii) Epstein-Barr virus, human cytomegalovirus, and Kaposi's sarcoma-associated herpesvirus; and (iii) HHV-6A, -6B, and -7. The method was validated with prequantified reference standards as well as with mucocutaneous swabs and cerebrospinal fluid, plasma, and tonsillar tissue samples. Our findings highlight the value of multiplexing in the diagnosis of many unsuspected, yet clinically relevant, herpesviruses. In addition, we report here frequent HHV-DNA co-occurrences in clinical samples, including some previously unknown. HERQ-9 exhibited high specificity and sensitivity (LOD95s of 10 to 17 copies/reaction), with a dynamic range of 101 to 106 copies/1. Moreover, it performed accurately in the coamplification of both high- and low-abundance targets in the same reaction. In conclusion, we demonstrated that HERQ-9 is suitable for the diagnosis of a plethora of herpesvirus-related diseases. Besides its significance to clinical management, the method is valuable for the assessment of hitherto-unexplored synergistic effects of herpesvirus coinfections. Furthermore, its high sensitivity enables studies on the human virome, often dealing with minute quantities of persisting HHVs.

ABSTRACT Infections with the nine human herpesviruses (HHVs) are globally prevalent and characterized by lifelong persistence. Reactivations can potentially manifest as life-threatening conditions for which the demonstration of viral DNA is essential. In the present study, we developed HERQ-9, a pan-HHV quantitative PCR designed in triplex reactions to differentiate and quantify each of the HHV-DNAs: (i) herpes simplex viruses 1 and 2 and varicella-zoster virus; (ii) Epstein-Barr virus, human cytomegalovirus, and Kaposi's sarcoma-associated herpesvirus; and (iii) HHV-6A, -6B, and -7. The method was validated with prequantified reference standards as well as with mucocutaneous swabs and cerebrospinal fluid, plasma, and tonsillar tissue samples. Our findings highlight the value of multiplexing in the diagnosis of many unsuspected, yet clinically relevant, herpesviruses. In addition, we report here frequent HHV-DNA co-occurrences in clinical samples, including some previously unknown. HERQ-9 exhibited high specificity and sensitivity (LOD₉₅s of ~10 to ~17 copies/reaction), with a dynamic range of 10¹ to 10⁶ copies/μl. Moreover, it performed accurately in the coamplification of both high- and low-abundance targets in the same reaction. In conclusion, we demonstrated that HERQ-9 is suitable for the diagnosis of a plethora of herpesvirus-related diseases. Besides its significance to clinical management, the method is valuable for the assessment of hitherto-unexplored synergistic effects of herpesvirus coinfections. Furthermore, its high sensitivity enables studies on the human virome, often dealing with minute quantities of persisting HHVs.

IMPORTANCE By adulthood, almost all humans become infected by at least one herpesvirus (HHV). The maladies inflicted by these microbes extend beyond the initial infection, as they remain inside our cells for life and can reactivate, causing severe diseases. The diagnosis of active infection by these ubiquitous pathogens includes the detection of DNA with sensitive and specific assays. We developed the first quantitative PCR assay (HERQ-9) designed to identify and quantify each of the nine human herpesviruses. The simultaneous detection of HHVs in the same sample is important since they may act together to induce life-threatening conditions. Moreover, the high sensitivity of our method is of extreme value for assessment of the effects of these viruses persisting in our body and their long-term consequences on our health.

KEYWORDS Epstein-Barr virus, HHV-6, coinfection, cytomegalovirus, diagnostics, human herpesviruses, multiplex, qPCR, quantitative methods, tonsils, viral persistence, virome

The nine human herpesviruses (HHVs) are ubiquitous pathogens that persist lifelong after primary infection. HHVs cause many disorders, ranging from mild mucocutaneous diseases to severe central nervous system conditions, birth defects, and cancer. Their ability to reactivate poses significant risks, particularly to immunosuppressed patients, such as transplant recipients, in whom Epstein-Barr virus (EBV), human cytomegalovirus (HCMV), HHV-6B, and Kaposi's sarcoma-associated herpesvirus (KSHV) can induce life-threatening conditions (1–8).

The investigation of active HHV infections includes, among other markers, the detection of viral nucleic acids, typically by quantitative PCR (qPCR). In addition, the simultaneous detection of these pathogens has been shown to be beneficial, as their recognition may be difficult based on the clinical presentation alone (9–15).

While several multiplex qPCRs have been introduced for detection of HHVs (16–19), none are designed to quantify them all. In addition, only few of the existing protocols distinguish between the closely related HHV-6A and HHV-6B, a distinction that may be crucial, as the former still lacks clear association to disease (20–23).

In the present study, we developed a pan-herpes multiplex assay, HERQ-9, that quantifies and discriminates each of the HHVs using three separate triplex-qPCRs: the first amplifies herpes simplex viruses 1 and 2 (HSV-1 and -2) and varicella-zoster virus (VZV), the second EBV, HCMV, and KSHV, and the third HHV-6A, -6B, and -7. We validated our assay using prequantified reference materials and evaluated its performance with various clinical samples as well as solid tissue material.

HERQ-9 simplifies diagnosis and improves the clinical management and risk assessment of highly susceptible populations (1, 5, 8, 24–26). Moreover, its high sensitivity is of significant value for studies on the impact of HHV persistence on health (27, 28) and disease (29, 30).

RESULTS

***In silico* evaluation of amplicons, primers, and probes.** The designed primers and probes were queried against all available sequences (full or partial genomes) in the NCBI database. The oligonucleotides showed perfect match for the different strains except for four sequences of HHV-6A (GenBank accession numbers [KY316054.1](#), [KT355575.1](#), [KY316056.1](#), and [KY316047.1](#)) and two of HCMV (GenBank accession numbers [KY490070.1](#) and [KP745685.1](#)) for which one to two mismatches were observed far from the 3' end.

We found no nonspecific binding to other viruses or human DNA except for the primers and probe of HSV-2, which also had complete homology to chimpanzee alpha-1 herpesvirus (GenBank accession number [JQ360576.1](#)).

In silico analysis of amplicons, primers, and probes revealed no relevant secondary structures, primer-dimers, or cross-dimers (see Fig. S1 and S2 in the supplemental material).

Analytical sensitivities and specificities. We evaluated the sensitivities using eight replicates of the respective plasmids in seven dilutions ranging from 50 copies to 1 copy per reaction. Based on probit link function, the limits of detection (LOD₉₅) of HERQ-9 for HSV-1, HSV-2, VZV, EBV, HCMV, KSHV, HHV-6A, HHV-6B, and HHV-7 were, respectively, 12, 13, 13, 10, 16, 17, 11, 11, and 11 copies per reaction. The values were similar in the singleplex format (see Fig. S3 in the supplemental material).

The multiplex assay detected all HHVs correctly from infected cell lines without cross-amplification of other HHVs, human DNA, or near-full-length or full-length genomes of parvovirus B19 (B19V) or the polyomaviruses BK virus (BKPv), JC virus (JCPv), and Merkel cell virus (MCPv). All the no-template water controls remained negative throughout the PCR analyses.

Repeatability and reproducibility. We tested the intra-assay and interassay variations in three separate qPCR runs using five replicates of the individual HHV plasmids (10^6 to 10^1 copies/ μ l) and plasmid mixes pMIXI (HSV-1 and -2 and VZV), pMIXII (EBV, HCMV, and KSHV), and pMIXIII (HHV-6A, -6B, and -7).

The assay showed excellent short-term repeatability and long-term reproducibility in both singleplex and multiplex formats as well as with pMIXI to -III. The highest standard deviations in quantification cycle (C_q) values (intra-assay) and coefficients of variation between runs (interassay) were seen at the lowest template copies (Tables 1 and 2).

The method was linear in the range of 10^1 to 10^6 copies per μ l, and the qPCR efficiencies were between 95.9% and 103.8% in all the experiments.

The HHV plasmid dilutions spiked with 500 ng of human DNA (HaCaT cells) showed equal linearity to pure HHV plasmids (Fig. 1; see also Fig. S4 in the supplemental material).

Comparison to prequantified reference samples. We correlated the quantification of HERQ-9 to several prequantified reference materials. The results are summarized in Table 3.

TABLE 2 Interassay variation

DNA from each of the two strains of HSV-1 and HSV-2 had spectrophotometrically estimated quantities of 4.3×10^9 and 6.1×10^9 copies/ μ l and 1.9×10^9 and 3.8×10^9 copies/ μ l, respectively. The calculated loads by our multiplex qPCR were 4.2×10^9 and 6.1×10^9 copies/ μ l for HSV-1 and 9.1×10^8 and 1.9×10^9 copies/ μ l for HSV-2. The conversion factors were hence 0.99 (HSV-1) and 0.49 (HSV-2).

A VZV DNA extract (ATCC) containing 5.6×10^5 copies/ μ l was calculated to have 1.8×10^6 copies/ μ l by HERQ-9, with a conversion factor of 3.2.

EBV, HCMV, and HHV-6B WHO international standards contained 1.0×10^4 , 1.0×10^4 , and 1.1×10^5 IU/ μ l, respectively. The calculated copies by HERQ-9 were 1.0×10^4 copies/ μ l for EBV, 3.2×10^4 copies/ μ l for HCMV, and 1.8×10^5 copies/ μ l for HHV-6B. Hence, the conversion factors (copies/international unit) were 1.0, 3.2, and 1.6, respectively.

Spectrophotometrically estimated copies of KSHV DNA were 2.2×10^9 copies/ μ l and calculated to be 5.0×10^9 copies/ μ l with our assay, yielding a conversion factor of 2.3.

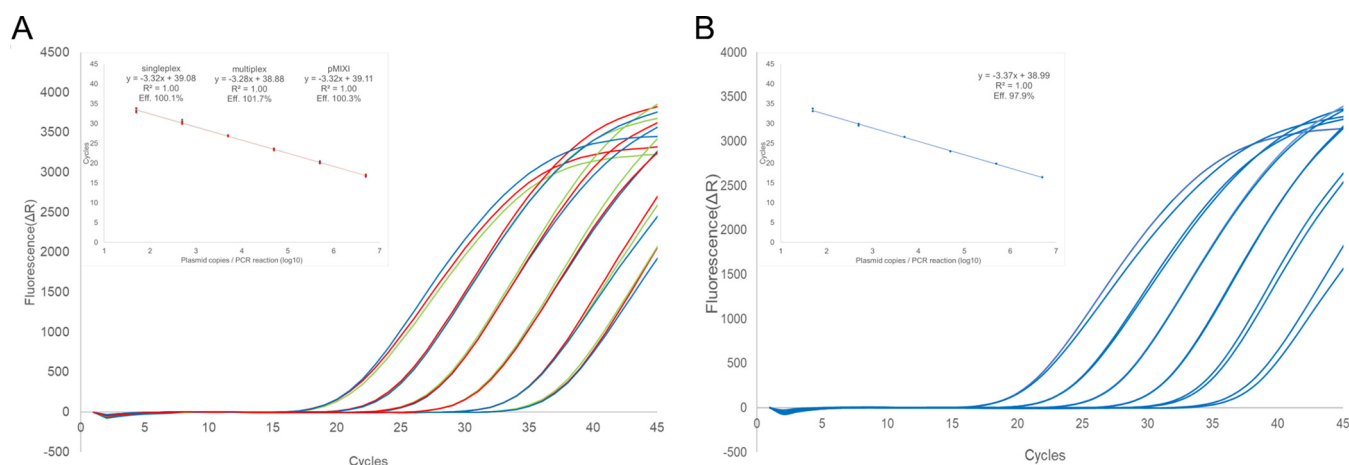

FIG 1 (A) Amplification and standard curves of HSV-1 plasmid dilutions from 10^6 to 10^1 copies/ μ l in singleplex format (red) or in multiplex format individually (green) or together with HSV-2 and VZV plasmids (pMIXI; blue). (B) pMIXI dilution series spiked with 500 ng/reaction of human DNA (HaCaT cells). The y axis represents baseline-corrected fluorescence signal (amplification curve) or cycles (standard curve). The x axis represents cycle number (amplification curve) or plasmid copies in the reaction (\log_{10}) (standard curve). Analogous illustrations for other herpesviruses can be found in Fig. S4.

HERQ-9 showed good correlation with HHV-6A, HHV-6B, and HHV-7 spiked in sera (Fig. 2). The conversion factors were 1.1, 1.3, and 6.8, respectively.

Analysis of clinical samples. We tested several types of clinical samples and compared the positive and negative agreements against reference methods. A summary of the results is presented in Table 4.

(i) Plasma. We tested 60 plasma samples, previously studied for EBV and/or HCMV at Turku University Hospital. Altogether, 13/13 and 16/16 plasma samples positive for EBV and HCMV by a reference qPCR, respectively, were positive by HERQ-9, with good correlation in viral loads (Fig. 3). Seven out of nine samples reported as borderline for EBV by the clinical laboratory (50 to 200 copies/ml of plasma) were positive in the new assay, as were four of five HCMV-borderline samples (50 to 200 copies/ml of plasma). Furthermore, the new qPCR found additional samples positive for EBV ($n = 3$) and HCMV ($n = 5$) that in the hospital laboratory had been tested only for one of the viruses. These samples were reanalyzed with a reference qPCR confirming one EBV and three HCMV positivities.

TABLE 3 Prequantified reference material

Virus	Sample type	Quantification method	Strain(s)	GenBank accession no.	No. of copies/ μ l		Conversion factor	Difference between quantifications (\log_{10})

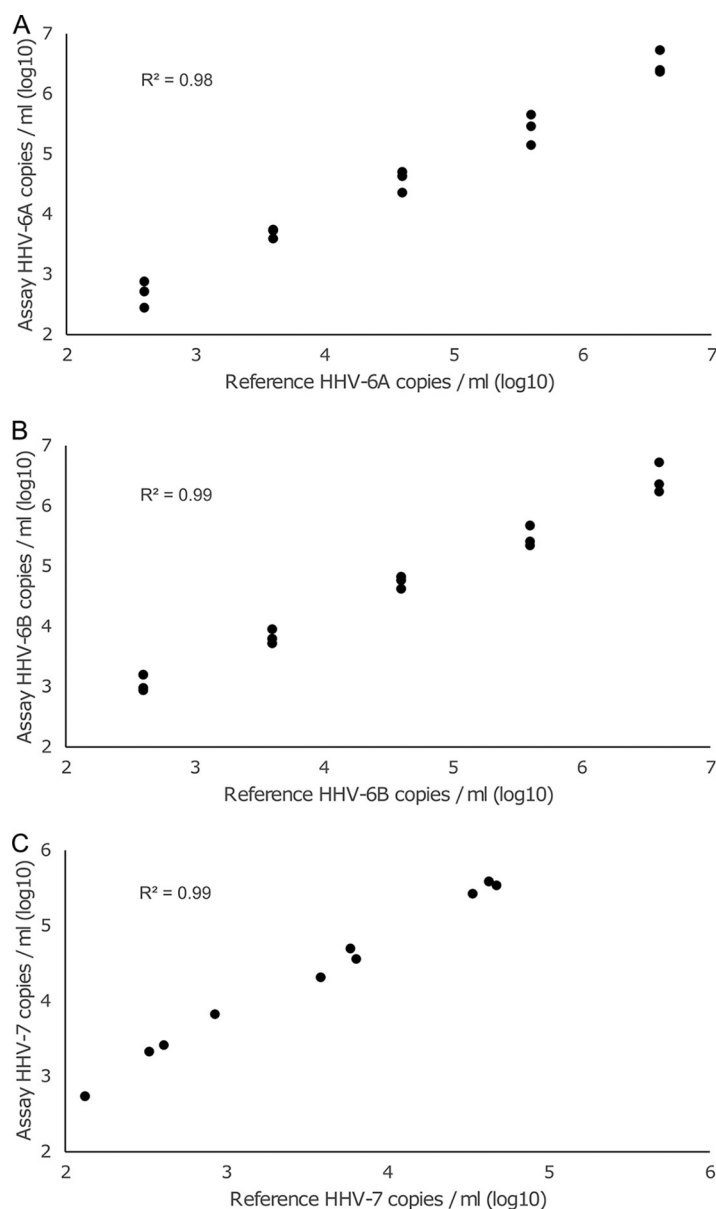

FIG 2 Reference copy numbers of serum samples spiked with HHV-6A (A), HHV-6B (B), and HHV-7 (C) plotted against copy numbers quantified by HERQ-9. Viral DNA copy numbers are presented per milliliter of serum (\log_{10} transformed). R^2 , coefficient of determination between the copy numbers.

Of the 60 plasma samples studied with HERQ-9, 6 were positive for HHV-6B (median, 2.7×10^2 copies/ml of plasma; range, 1.7×10^2 to 5.2×10^3), 1 was positive for HHV-6A (6.3×10^2 copies/ml of plasma), and 5 were positive for HSV-1 (median, 1.2×10^4 copies/ml of plasma; range, 8.0×10^2 to 5.1×10^4). The co-occurrence of HHVs in plasma was seen for 14 patients, of whom 3 had EBV/HCMV/HSV-1, 1 had EBV/HCMV/HHV-6B, 1 had EBV/HHV-6B/HSV-1, 5 had EBV/HCMV, 2 had EBV/HHV-6B, 1 had HCMV/HHV-6B, and 1 had EBV/HSV-1 (Fig. 4A).

(ii) Mucocutaneous swabs. We tested 114 mucocutaneous swab samples previously investigated for HSV-1 and -2 or VZV at Turku University Hospital.

HERQ-9 identified correctly all the mucocutaneous swab samples that had tested positive by rapid viral culture for HSV-1 ($n = 35$; median, 5.6×10^7 ; range, 1.4×10^5 to 8.2×10^9 copies/ml of collection medium) and HSV-2 ($n = 30$; median, 3.3×10^7 ; range, 2.9×10^5 to 3.5×10^8 copies/ml of collection medium). In contrast, the 15 culture-

^aPositive agreement with samples reported borderline with reference assay.

negative controls showed no amplification for HSV-1 or HSV-2. However, two of these negative samples were positive instead for VZV, at 2.0×10^7 and 3.2×10^4 copies/ml of collection medium, and were confirmed to be VZV DNA positive with a control PCR (4, 31). In addition, 5/5 HSV-1-positive and 4/4 HSV-2-positive DNA extracts previously tested by a reference PCR (4, 31) were also positive by HERQ-9.

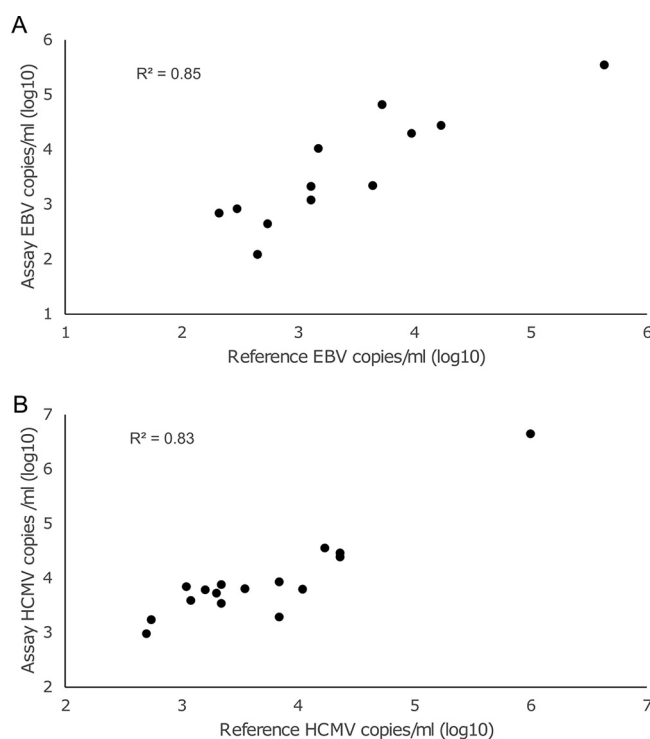

FIG 3 Comparison of EBV (A) and HCMV (B) quantities (copies/milliliter of plasma in \log_{10}) as determined by HERQ-9 and GeneProof EBV and CMV PCR kit reference assays.

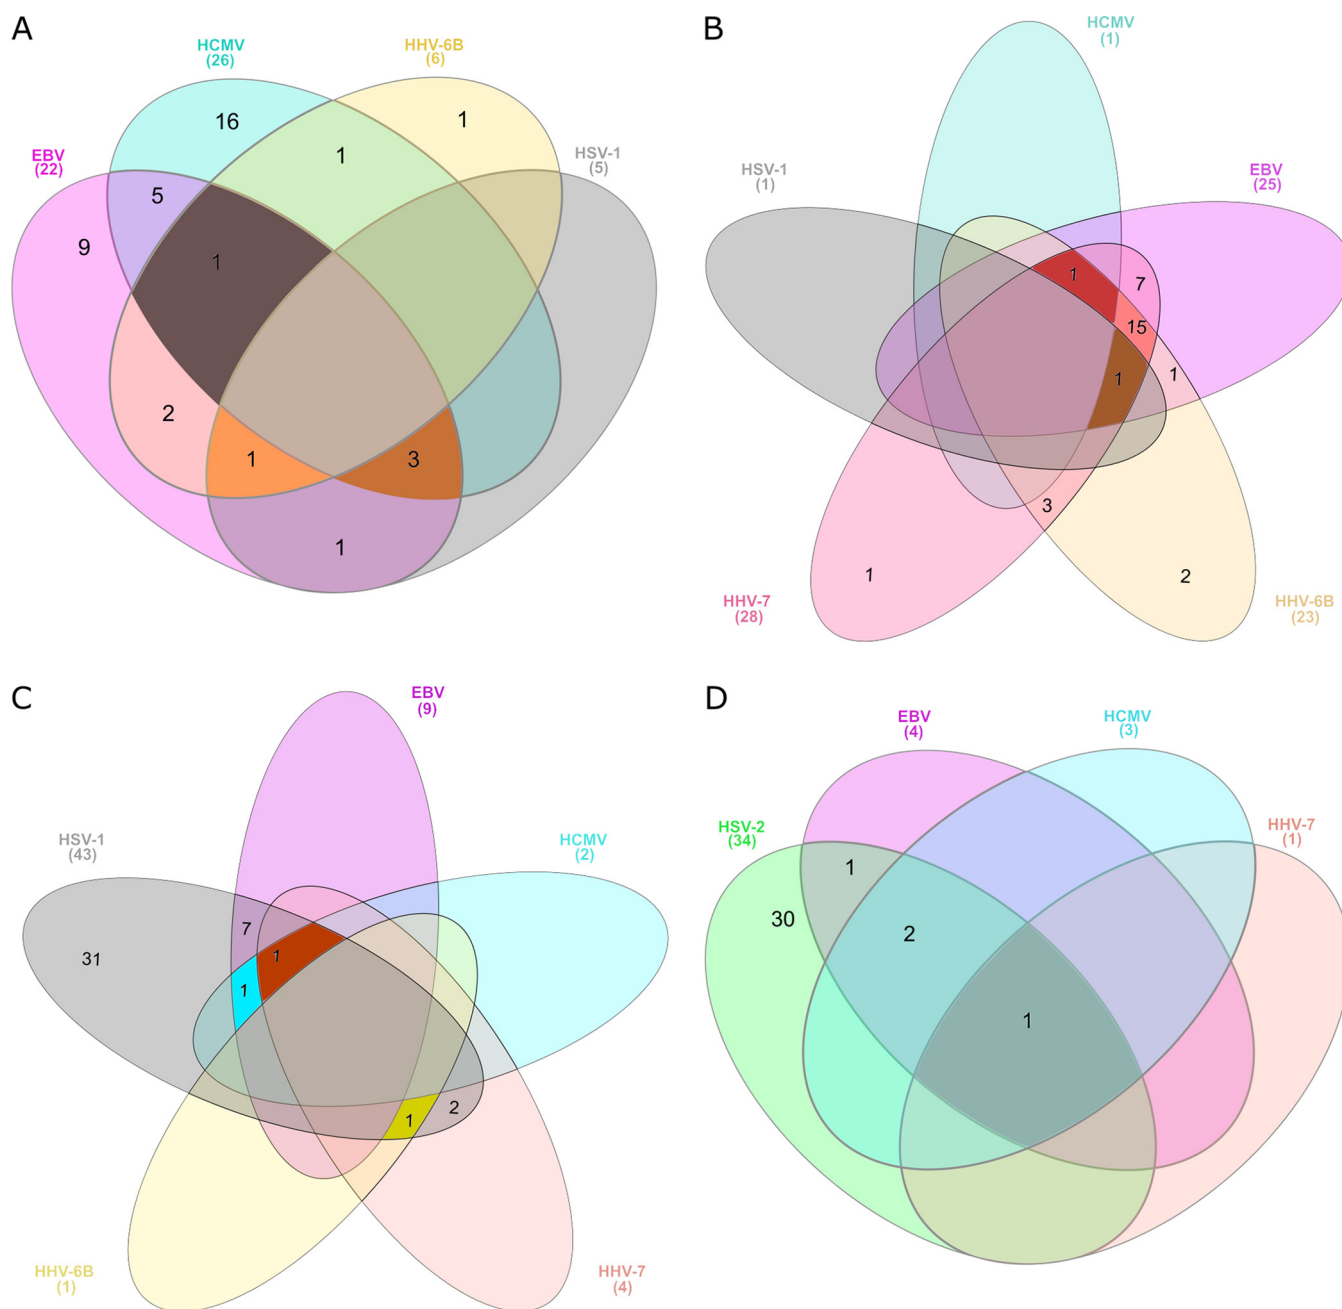

FIG 4 Venn diagrams representing HHV co-occurrence in 60 plasma samples (A), 35 palatine tonsils (B), 43 HSV-1-positive mucocutaneous swab samples (C), and 34 HSV-2-positive mucocutaneous swab samples (D). *n*, number of positive cases.

All the VZV samples positive ($n = 15$) by enzyme immunoassay (EIA) were positive by the new assay, at a median quantity of 4.5×10^7 copies/ml of collection medium (range, 8.0×10^6 to 2.7×10^9). On the other hand, among 10 VZV antigen-negative samples, 2 contained VZV DNA at 3.6×10^6 and 4.7×10^3 copies/ml of collection medium. Of these, the former was confirmed to be VZV DNA positive by the reference PCR. Incidentally, among the remaining eight samples negative for the VZV antigen, three showed positivity for HSV-1 instead, at loads of 7.7×10^7 , 7.2×10^7 , and 6.3×10^1 copies/ml of collection medium. Only the two samples with the highest copy numbers were confirmed to be positive for HSV-1 DNA by the control PCR.

Moreover, we codetected other HHVs in these mucocutaneous swabs (Fig. 4C and D). Of the HSV-1-positive samples, 20.9% were also positive for EBV DNA, 4.7% for

FIG 5 Prevalences and copy numbers per million cells of HHV-6B, HHV-7, EBV, HSV-1, and HCMV in tonsillar tissues. Notches represent interquartile ranges (IQRs) of the samples and whiskers the range ± 1.5 IQRs from the upper and lower quartiles.

HCMV DNA, 9.3% for HHV-7 DNA, and 2.3% for HHV-6B DNA. Among the HSV-2-positive swabs, 5.3% were also positive for EBV, 8.8% for HCMV, and 2.9% for HHV-7. Of 19 VZV-positive swabs, 1 was positive for EBV-DNA (5.3%). Of all the 114 swabs, 2 were quadruply positive (HSV-1/EBV/HCMV/HHV-7 and HSV-2/EBV/HCMV/HHV-7) and 4 were triply positive (HSV-1/EBV/HCMV, HSV-1/HHV-6B/HHV-7, and two HSV-2/EBV/HCMV). The copy numbers of the other codetected HHVs (generally \log_2 to \log_3 copies/ml of collection medium) were always lower than those for HSV-1, HSV-2, or VZV. However, a few samples had \log_5 to \log_6 copies/ml of EBV DNA. Of all the mucocutaneous swab samples negative for HSV-1, HSV-2, and VZV ($n = 18$), one (5.6%) tested positive for EBV DNA.

(iii) CSF. Eight cerebrospinal fluid (CSF) samples were analyzed with the pan-herpes multiplex assay. Two were positive for VZV (3.23×10^3 and 1.64×10^5 copies/ml of CSF), in concordance with the hospital laboratory reference PCR (4, 31).

HHV prevalences in tonsillar tissue. The HHV DNA prevalences in 35 tonsillar tissue samples were 80% for HHV-7, 71% for EBV, 66% for HHV-6B, 3% for HSV-1, and 3% for HCMV. No HSV-2, VZV, or KSHV was found (Fig. 5). Of these samples, 2 were positive for four HHVs, 17 for three, and 10 for two, while four tonsils were negative for all the HHVs (Fig. 4B). The median viral loads (copies/million cells) were highest for EBV (2.1×10^2 ; interquartile range [IQR], 9.6×10^1), followed by HHV-7 (3.6×10^1 ; IQR, 1.3×10^2) and HHV-6B (1.1×10^1 ; IQR, 2.2×10^1).

Coquantification of mixed high- and low-abundance targets. We tested uneven copies of whole HHV genomes in the same reaction (range, 4.5×10^0 to 1.1×10^6 copies/ μ l) and found that all the viruses were correctly differentiated and accurately quantified by HERQ-9 (Pearson correlation coefficient [r] = 0.996, $P < 0.01$). Higher coefficients of variation were seen at lower viral copy numbers (Table 5).

DISCUSSION

Our newly developed pan-herpes multiplex-qPCR assay, HERQ-9, stands out for its ability to differentiate and quantify the genomes of all nine human herpesviruses.

HERQ-9 was designed on three distinct triplex-qPCRs to meet, on the one hand, the clinical needs and, on the other, the technical constraints inherent to PCR multiplexing. Indeed, the capacity to codetect several targets is restricted by the spectral overlap of different fluorophores as well as the number of channels in the qPCR instrument

TABLE 5 Three viral genomes intermixed into the same reaction^a

Virus mix	Estimated viral genome copies/ μ l			Measured viral genome copies/ μ l		
	HSV-1	HSV-2	VZV	HSV-1	HSV-2	VZV

^aOn the left are the estimated genome copies per dilution and on the right the copy numbers per microliter of DNA extract quantified by HERQ-9. In parentheses are the coefficient of variations (percent) between the estimated and measured copy numbers. Estimated and measured viral genome copies showed significant correlation (Pearson's $r = 0.996$; $P < 0.01$).

(maximum of six) (32). Moreover, a greater number of targets can increase cross-reactions between primers and probes, hampering assay performance.

The new multiplex assay performed remarkably well on cell, plasma, and CSF samples and mucocutaneous swabs as well as on palatine tonsils. HHV genoprevalences in this lymphoid organ have been reported to be highest for EBV (20.4 to 88.8%), followed by HHV-7 (71.4%), HHV-6B (50.7%), HSV-1 (1.8 to 6.3%), and HCMV (0 to 5.4%) (33–35), in line with our results. In addition, we frequently codetected several HHVs in the same tonsil, a phenomenon only previously reported by Berger et al. for young children (36).

HERQ-9 had good agreement with reference materials. The observed dissimilarities were likely to be related to the types and sensitivities of different methodologies (e.g., viral culture, EIA, and spectrophotometry), sample processing (e.g., DNA extraction methods), and the design of the PCR methods compared. Regarding the last item, the primer and probe design, amplicon size, target gene and its polymorphisms, reagents, and standards can all account for disagreements between qPCRs (37–39). In fact, these discrepancies have urged the introduction of WHO international standards for EBV, HCMV, and HHV-6B to increase the commutability between assays (39–42). However, this has had only relative value since, even after standardization, the interlaboratory variabilities continue to be high (up to $1.5 \log_{10}$ IU/ml, on average) (39, 42).

Our findings emphasize the importance of multiplexing for comprehensive diagnosis and clinical management. Indeed, we identified additional HHVs in clinical samples that had been tested only for a single pathogen, encountering several unforeseen HSV-1 or VZV findings in mucocutaneous swabs, as well as EBV-HCMV coreactivations in plasma of immunodeficient patients. In addition, we codetected other HHVs in plasma in several combinations (EBV/HSV-1, EBV/HHV-6B, HCMV/HHV-6B, EBV/HCMV/HSV-1, EBV/HCMV/HHV-6B, and EBV/HHV-6B/HSV-1). These coincidental discoveries, also noted by others (4, 19, 43), may have a significant impact on risk assessment and prognosis. Indeed, HHVs are thought to individually or synergistically contribute to viral syndromes (5, 8, 44), organ rejection (19), or the development of cancer (45, 46).

Moreover, we found other HHVs besides HSV-1, HSV-2, or VZV in mucocutaneous lesions (up to four in the same sample). The most common were EBV, HCMV, and HHV-7, whose low viral loads were likely to represent skin virome (47) or latency in

mobilized leukocytes (48). Yet in a few samples, EBV DNA levels approached those of HSV-1 or HSV-2, suggestive of *in situ* coreactivation or coinfection. Our detection of both EBV and HSV-1 in mucocutaneous lesions and plasma supports an interplay between these two viruses, as has been shown *in vitro* by Wu et al. (49). To the best of our knowledge, we are the first to report on HHV co-occurrences in classical herpetic lesions.

In conclusion, we demonstrated that HERQ-9 is suitable for the diagnosis of a plethora of herpesvirus-related diseases. Besides its significance for clinical management, the high sensitivity and specificity of this method will be of particular value for studies of the human virome generally dealing with minute quantities of persisting HHVs.

MATERIALS AND METHODS

Plasmids. Sequences of the reference strain (90 to 336 bp), including the corresponding qPCR amplicon, were inserted into a pDTSmart backbone (Integrated DNA Technologies). The plasmids (pHSV-1, pHSV-2, pVZV, pHHV-6A, pHHV-6B, pHHV-7, pEBV, pHCMV, and pKSHV) were transformed into *Escherichia coli*, extracted (see “DNA extraction” below), and confirmed with restriction analysis to contain the correct insert (for whole insert sequences, see Text S1 in the supplemental material). The concentrations were measured spectrophotometrically, and the plasmids (diluted serially from 10^6 to 10^1 copies/ μ l in 10 mM Tris-EDTA [TE] buffer) were stored at -80°C . In addition to single-plasmid analysis, triple-plasmid combinations were made: pHSV-1, pHSV-2, and pVZV (pMIXI); pEBV, pHCMV, and pKSHV (pMIXII); and pHHV-6A, pHHV-6B, and pHHV-7 (pMIXIII).

Plasmids containing the full-length or near-full-length genome of parvovirus B19 genotype 1 (50) and polyomaviruses BKPyV (NC_001538) and JCPyV (NC_001699) (generous gifts from Eeva Auvinen) and MCPyV (inserted in vector backbone pJ241, a gift from Patrick Moore [51]; Addgene plasmid 32059) were used to test nonspecific amplification.

Infected cell cultures. Primers and probes were initially tested using viral DNA extracted from virus-infected cell cultures. HSV-1 (strain F), HSV-2 (strain G), and VZV (strain Ellen) were propagated in HaCat cells, human foreskin fibroblasts, and Vero cells; EBV was propagated in Raji cells, HCMV (strain AD169) in human lung fibroblasts (MRC-5), HHV-6A (strain GS) in HSB-2 cells, HHV-6B (strain Z29) in MOLT-3 cells, HHV-7 (strain JI) in SupT-1 cells, and KSHV (strain rKSHV.219) in latent and lytic iSLK.219 cells (52).

Uninfected HaCaT cells were used for human DNA spiking experiments.

Prequantified reference material. All the reference materials are presented in Tables 3 and 4.

(i) Cell-free viral nucleocapsids. HSV-1 and HSV-2 nucleocapsids were isolated from pseudonymized dermal or mucosal lesion samples at the virus diagnostic unit of Turku University Hospital. The viruses were initially typed by a rapid viral culture immunoperoxidase assay (53) and confirmed by HSV type-specific gD (US6) gene-based PCR (54). For viral nucleocapsid DNA preparations, low-passage-number stocks were generated in Vero cells (African green monkey kidney; ATCC), and the viral genomic DNA was prepared as described previously (55, 56) (see Text S2 in the supplemental material for a more detailed description). Two strains of HSV-1 (HSV-H1211 and HSV-H1215) and HSV-2 (HSV2-H12211 and HSV2-H1526) were prepared and the viral copies determined spectrophotometrically to be used as reference standards in dilutions of 1:10,000 and 1:100,000.

(ii) WHO international standards. WHO international standards for EBV, HCMV, and HHV-6B (NIBSC codes 09/260, 09/162, and 15/266, respectively) (57–59) were tested undiluted and in dilutions of 1:10 and 1:100 with HERQ-9, to obtain conversion factors (viral DNA copies/international units).

(iii) KSHV genome in bacterial artificial chromosome (BAC). KSHV-BAC16 DNA (a generous gift from Carolina Arias, University of California, Santa Barbara [UCSB], CA), derived from the KSHV strain of primary effusion lymphoma (PEL) cell line JSC-1, was purified from *E. coli* (60). The viral copy numbers were estimated spectrophotometrically. This reference was analyzed in dilutions of 1:10,000, 1:100,000, and 1:1,000,000 with the multiplex assay.

(iv) Spiked sera. Serum samples spiked with HHV-6A ($n = 15$) or HHV-6B ($n = 15$) (4×10^6 to 4×10^2 copies/ml of serum) and HHV-7 ($n = 12$) were obtained from the HHV-6 Foundation (Santa Barbara, CA). Reference copy numbers given by the providing institute were used for HHV-6A and HHV-6B (59), while the HHV-7 DNA was quantified with a commercial HHV-7 qPCR kit (PCRmax) in our laboratory.

(v) ATCC standard. Quantitative genomic DNA of VZV (ATCC VR1367DQ) was analyzed with HERQ-9 undiluted and at 1:10 and 1:100 dilutions.

Clinical samples. All the clinical HHV samples were collected at the virus diagnostic unit of Turku University Hospital, and details are presented in Table 4. These included 80 mucocutaneous swab samples, of which 35 were positive for HSV-1 and 30 for HSV-2 by rapid viral culture immunoperoxidase assay (53), 25 mucocutaneous swab samples, of which 15 were positive for VZV by antigen enzyme immunoassay (61), 5 HSV-1 and 4 HSV-2 PCR-positive DNA extracts from mucocutaneous swab samples tested by a reference PCR (4, 31), and 8 CSF samples, of which 2 were VZV positive by a control PCR (4, 31).

In addition, 60 plasma samples were investigated, of which 17 had been studied only for EBV (GeneProof EBV PCR kit), 17 only for HCMV (GeneProof CMV PCR kit), and 26 for both. Of these, 13 and

^aNucleotides in brackets refer to locked nucleic acids.

16 samples were reported as EBV and HCMV positive (>200 copies/ml of plasma), respectively, while 9 and 5 had borderline copy numbers (50 to 200 copies/ml of plasma).

Tonsillar tissues. Altogether, 35 mechanically homogenized tonsillar tissues were screened for the nine HHVs. The patients were 2 to 69 years of age (mean, 26), with eight <12 years (48). The viral loads were normalized per 10⁶ cells, determined with the human single-copy gene RNase P qPCR (48).

Herpesvirus DNA mixes. Mixtures of three viral genomes extracted from the previously mentioned infected cell lysates ([i] HSV-1, HSV-2, and VZV and [ii] EBV, HCMV, and KSHV) or spiked serum ([iii] HHV-6A, -6B, and -7) were tested at uneven quantities, ranging from 4.5 × 10⁰ to 1.1 × 10⁶ copies/μl of DNA extract.

Primers and hydrolysis probes. Primers and probes were designed for all HHVs, except for EBV (62). For each virus, several primer pairs were constructed *in silico*, in conserved genes (16, 18, 63, 64). Degenerate primers were designed for HCMV to cover polymorphisms in the target area. Moreover, for HHV-6A, two probes were custom-designed to contain six locked nucleic acids (LNA) each (for shorter probe length) and a single-nucleotide difference for specific binding to different strains (Table 6).

The tendency of primers and probes to form secondary structures, primer dimers, and cross-dimers was evaluated with Multiple Primer Analyzer (Thermo Fisher Scientific), while the propensity of the amplicons to form secondary structures was checked with the Mfold web server. A BLAST search (65) was performed to confirm primer binding to each of the virus strains in the nucleotide collection database (NCBI).

Primer candidates designed *in silico* were tested at a 200 nM concentration with plasmid dilutions (see “Plasmids” above), human DNA (HaCaT; 500 ng/reaction), and nuclease-free water in a SYBR green format (Maxima SYBR green qPCR master mix; Thermo Fisher Scientific), followed by melting-curve analysis. Primer pairs showing the highest efficiency and sensitivity with no primer dimer formation were chosen for further testing with the hydrolysis probes. Concentrations of the

primer pairs were optimized empirically with a matrix of reactions ranging from 100 nM to 600 nM. The probes were tested in a 100 nM to 400 nM range. The final primer and probe concentrations are presented in Table 6.

Primers and hydrolysis probes were purchased as high-performance liquid chromatography (HPLC) purified except for two degenerative primers (HCMV), which were cartridge purified (Sigma-Aldrich). For the triplex reactions, the probes were labeled with 6-carboxyfluorescein–black hole quencher 1 (FAM-BHQ1), 6-carboxy-4',5'-dichloro-2',7'-dimethoxyfluorescein (JOE)-BHQ1, and sulforhodamine 101 acid chloride-BHQ2 (TxRed).

Quantitative PCR protocol. Four commercial master mixes were pretested with HSV-1, HSV-2, and VZV plasmids and viral genomes, with special consideration given to the performance in the presence of human DNA and the coamplification of markedly low- and high-abundance targets. Consequently, TaqPath ProAmp multiplex master mix (Thermo Fisher Scientific) was chosen for the multiplex assay.

The qPCR thermal profile comprised initial denaturation at 95°C for 10 min followed by 45 cycles of 15 s at 95°C and 60 s at 60°C. The qPCRs contained 5 µl of template, 2× TaqPath ProAmp multiplex master mix, primers and probes (Table 6), and nuclease-free water in a final volume of 20 µl. Water was used as negative control in all the qPCR runs. The samples were run in duplicate in AriaMx real-time PCR system (Agilent) and analyzed with Aria real-time PCR software (v.1.3) provided by the manufacturer. The adaptive fluorescence baseline, efficiency, slope, R^2 values, and intercept were calculated by the software. Background-based threshold was set for cycles 5 to 9 for the FAM and Texas Red dyes and 8 to 11 for the JOE dye.

Pretesting of primers in the SYBR green format consisted of the above-mentioned thermal profile, followed by a melting-curve analysis at 95°C for 60 s, 45°C for 30 s, and 95°C for 30 s. The melting-curve analysis was performed with a resolution of 0.5°C and soak time of 5 s.

DNA extraction. DNAs from plasma, mucocutaneous swabs, CSF, and WHO international standards were extracted from 200 µl of starting material with the QIAamp DNA blood minikit (Qiagen), DNAs from cells and virus-infected cell lines were extracted with the QIAamp DNA minikit (Qiagen), DNA from KSHV BAC was extracted with the NucleoBond Xtra Midi EF kit (Macherey-Nagel), and transformed plasmids were extracted with GeneJET plasmid miniprep kit (Thermo Fisher Scientific), according to the manufacturers' instructions. The final elution volumes were 100 µl (with the exception of 50 µl for plasma and 60 µl for CSF samples). In every extraction, at least two negative controls (phosphate-buffered saline) were included.

Analytical sensitivity and specificity. The analytical sensitivities were determined in singleplex and multiplex formats using eight replicates of each HHV plasmid template in 50, 25, 15, 10, 5, 3, and 1 copy per reaction. The proportion of positive results was fit into a generalized linear model using probit link function (MATLAB v.R2018b) to approximate the limit of detection (LOD_{95}) for a given target.

The analytical specificities were evaluated by cross-testing (i) 10^7 copies of viral genomic DNA extracted from infected cell lysates and plasmid constructs of each HHV and (ii) plasmids containing near full-length or full-length genomes of polyomaviruses BKPyV, JCPyV, and MCPyV and parvovirus B19 genotype 1. In addition, 1,000 ng of cellular DNA extracted from HaCaT cells and 500 ng from human foreskin fibroblasts were tested for nonspecific amplification of human DNA.

Repeatability and reproducibility. The intra-assay and interassay variations were calculated using three separate qPCR runs using five replicates of HHV plasmids (10^6 to 10^1 copies/µl) in the singleplex and multiplex formats, the latter both as single plasmids or in mixes pMIXI, pMIXII, and pMIXIII (10^6 to 10^1 copies/µl). Two of the replicates were used to generate a standard curve, and three were marked as unknowns. The standard deviations of the C_q values of the five replicates were used as a measure of intra-assay variation. A coefficient of variation calculated from the copy numbers of unknown replicates from three separate runs was used to estimate the interassay variation.

Statistical analysis. Boxplots were built with Rstudio (v.1.2.5001), and Excel 2016 (v.16.0.4964.1000) was used to create scatterplot graphs. Pearson correlation coefficient between estimated and quantified copies in virus mixes was calculated with SPSS (v.25). Venn diagrams were made with InteractiVenn (66).

Ethics statement. The Ethics Committee of the Helsinki and Uusimaa Hospital District approved the collection of tonsils. Informed consent was obtained from all the donors or their parents prior to the surgery.

ACKNOWLEDGMENTS

We thank Leena-Maija Aaltonen for collecting the tonsil samples and Ritva Kajander and Huda Habib for help in the preparation of the viral DNA from HSV-1 and -2 nucleocapsids.

The study was supported by the Finnish Medical Foundation (FLS), the Orion Research Foundation, the Finnish Society for Study of Infectious Diseases, the Emil Aaltonen Foundation, the Finnish-Norwegian Medical Foundation, the Instrumentarium Science Foundation, the Biomedicum Helsinki Foundation, the Magnus Ehrnrooth Foundation, the Finnish Society of Sciences and Letters, the Finnish Cultural Foundation, the Juhani Aho Foundation for Medical Research, the Jane & Aatos Erkko Foundation, the Academy of Finland, the University of Helsinki Doctoral Programme in Biomedicine, and the Research Funds of University of Helsinki and Helsinki University Hospital.

We declare no conflicts of interest.

L.P., M.T., K.H., H.V., and M.F.P. contributed to the design of this study. C.S. and H.V. planned the target gene areas. L.P., M.J., and H.S. executed the development of the qPCR and optimization experiments. L.P. carried out experiments with clinical and reference samples and analyzed the data. H.V., M.F.P., V.H., E.E., and P.M.O. participated in the collection of reference materials. T.V. and H.V. coordinated the collection of clinical samples. L.P. and M.F.P. drafted the manuscript. K.H., M.T., M.J., H.S., P.M.O., E.E., V.H., and H.V. participated in writing of the manuscript. All authors read and approved the final manuscript.
